Sequential modelling

Attention and self-attention

Transformers

Language and vision transformers

Sequence2sequence models

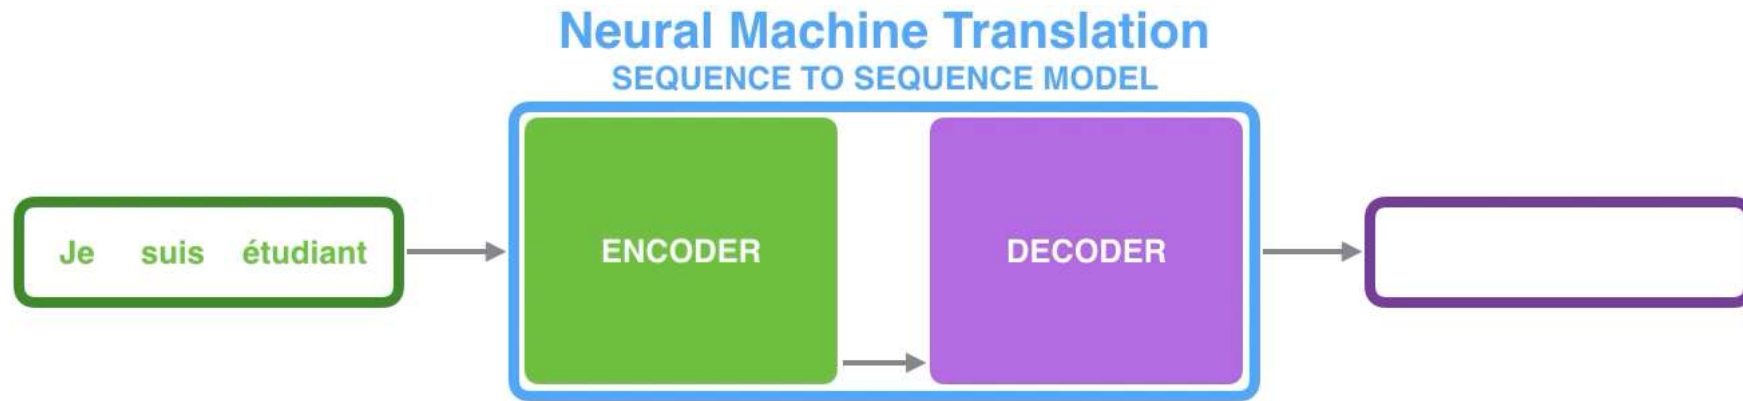

Encoder-decoder models with 2 parts:

1. **Encoder:** takes a variable-length sequence of elements as the input and transforms it into a context representation with a fixed-size.
2. **Decoder:** maps the encoded state of a fixed size to a variable-length sequence of elements.

Was a backbone for many problems, especially in language processing

Sequence2sequence example

Encoder: reads sentence in one language and converts to context vector.

Decoder: outputs a translation from context vector.

Sequence2sequence example: encoder

An encoder encodes the input sentence, a sequence of vectors $x = (x_1, x_2, \dots x_{T_x})$, into a context vector c .

A common approach is to use an RNN/LSTM, such that:

$$h_t = f(x_t, h_{t-1}),$$
$$c = q(\{h_1, \dots h_{T_x}\}).$$

$h_t \in \mathbb{R}$ is a hidden state at time-step t ,

c is the context vector generated from the sequence of states,

f and q are nonlinear functions.

$$h_t = f(x_t, h_{t-1}) \quad c = q(\{h_1, \dots h_{T_x}\})$$

Sequence2sequence example: decoder

The decoder is trained to predict the next word y_t , given the context vector c and all the previously predicted words $\{y_1, \dots, y_{t-1}\}$.

It defines a probability over the translation y by decomposing the joint probability into the conditionals:

$$p(y) = \prod_{t=1}^T p(y_t | \{y_1, \dots, y_{t-1}\}, c), \text{ where } y = (y_1, \dots, y_{T_y}).$$

With an RNN decoder, each conditional probability is modeled as:

$$p(y_t | \{y_1, \dots, y_{t-1}\}, c) = g(y_{t-1}, s_t, c), \text{ where}$$

g is a nonlinear (multi-layered) function $h_t = f(x_t, h_{t-1})$ $c = q(\{h_1, \dots, h_{T_x}\})$

Limitation of seq2seq models

The model needs to compress all necessary information of a source sequence into the fixed-length context vector c , i.e., there is a bottleneck.

The context is a vector of floats, and its size is the number of hidden units in the encoder RNN.

When dealing with long sequences, it is challenging for the model to compress all information into a fixed-length context — due to vanishing gradients.

A simple solution: attention

Attention strives to overcome the bottleneck issue of the encoder-decoder.

Allows the model to focus on all relevant inputs to decode the output.

Neural Machine Translation example: for every new word to generate, the model searches for a set of positions in the input where the most relevant information is concentrated.

A huge breakthrough in language processing, and later in all other domains.

Attention

Stop encoding the whole input in a fixed-length vector.

Instead encode the input into a sequence of vectors.

Then focus on a subset of these vectors adaptively while decoding the output.

I.e., simply stop squashing all information!

Attention formally

Now each conditional probability of the decoder is defined as:

$$p(y_t|\{y_1, \dots, y_{t-1}\}, x) = g(y_{t-1}, s_i, c_i), \text{ where}$$

s_i is a hidden state for time i , computed by:

$$s_i = f(s_{i-1}, y_{i-1}, c_i).$$

The probability is conditioned on a distinct context vector c_i for each target word y_i (unlike the conventional encoder-decoder).

The context vector c_i depends on a sequence of annotations (h_1, \dots, h_{t-1}) to which an encoder maps the input sentence.

Each annotation h_i contains information about the whole

Attention formally

The context vector c_i is computed as a *weighted sum* of these annotations h_j :

$$c_i = \sum_{j=1}^{T_x} \alpha_{ij} h_j,$$

where the weight α_{ij} of each annotation h_j is computed by the probability:

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{T_x} \exp(e_{ik})},$$

where $e_{ij} = a(s_{i-1}, h_j)$ is an alignment model,

It scores how well the inputs around position j and the output at position i match.

The alignment model a is parametrized as a feedforward

Attention formally

The weight α_{ij} reflects the importance of the annotation h_j , with respect to the previous hidden state s_{i-1} when deciding the next state s_i and generating y_i .

This implements a mechanism of attention in the decoder.

The decoder decides which parts of the source sentence to pay attention to.

Fig. 1 Graphical illustration of attention model trying to generate the t -th target word y_t given a source sentence $(x_1, x_2, \dots, x_T)^1$

Visualizing attention

<https://jalammar.github.io/visualizing-neural-machine-translation-mechanics-of-seq2seq-models-with-attention/>

The x-axis and y-axis correspond to the words in the source sentence (English) and the generated translation (French). Each pixel shows the weight α_{ij} of the annotation of the j -th source word for the i -th target word.

Self-attention

Self-attention (or intra-attention): relates parts of sequence with each other.

Results is a representation of the whole sequence.

In general terms, it can be seen as an operation on sets of elements.

Abstract

The dominant sequence transduction models are based on complex recurrent or convolutional neural networks that include an encoder and a decoder. The best performing models also connect the encoder and decoder through an attention mechanism. We propose a new simple network architecture, the Transformer, based solely on attention mechanisms, dispensing with recurrence and convolutions entirely. Experiments on two machine translation tasks show these models to be superior in quality while being more parallelizable and requiring significantly less time to train. Our model achieves 28.4 BLEU on the WMT 2014 English-to-German translation task, improving over the existing best results, including ensembles, by over 2 BLEU. On the WMT 2014 English-to-French translation task, our model establishes a new single-model state-of-the-art BLEU score of 41.0 after training for 3.5 days on eight GPUs, a small fraction of the training costs of the best models from the literature.

The transformer

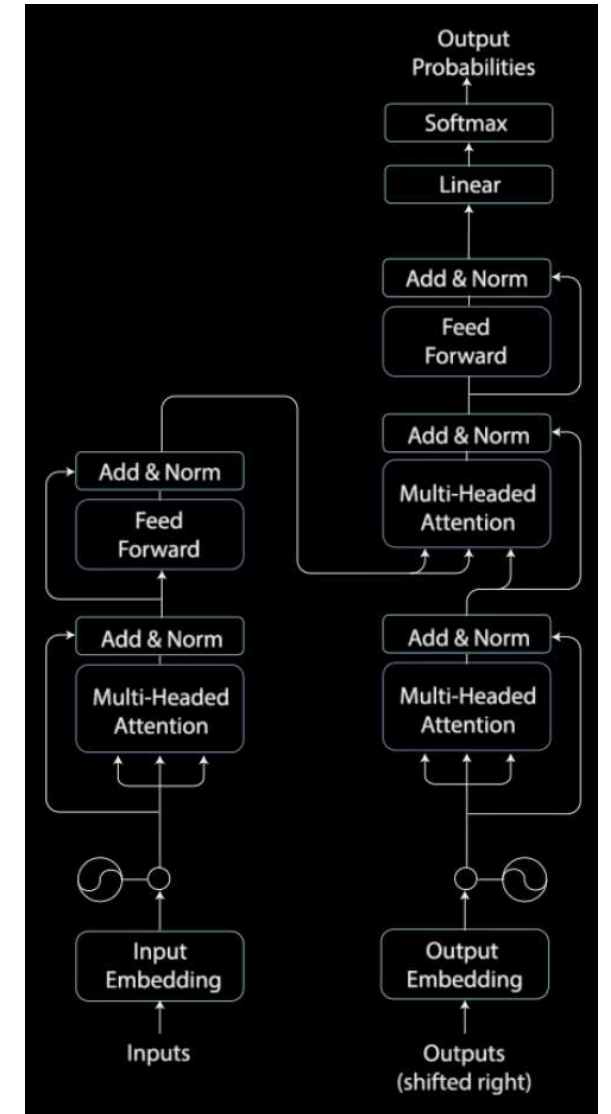

An encoder-decoder model based on (self-)attention mechanisms:

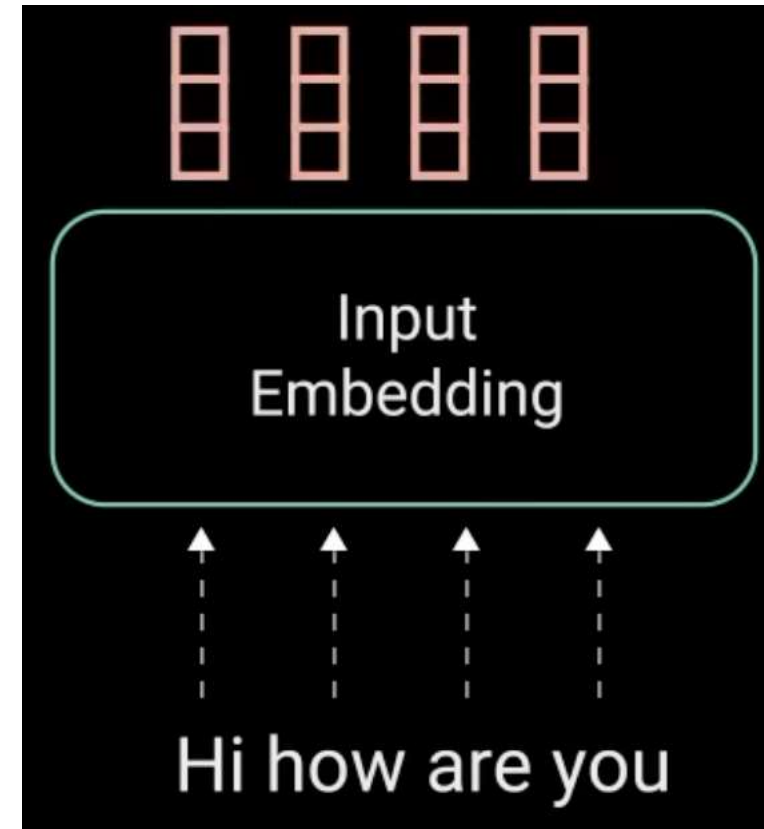

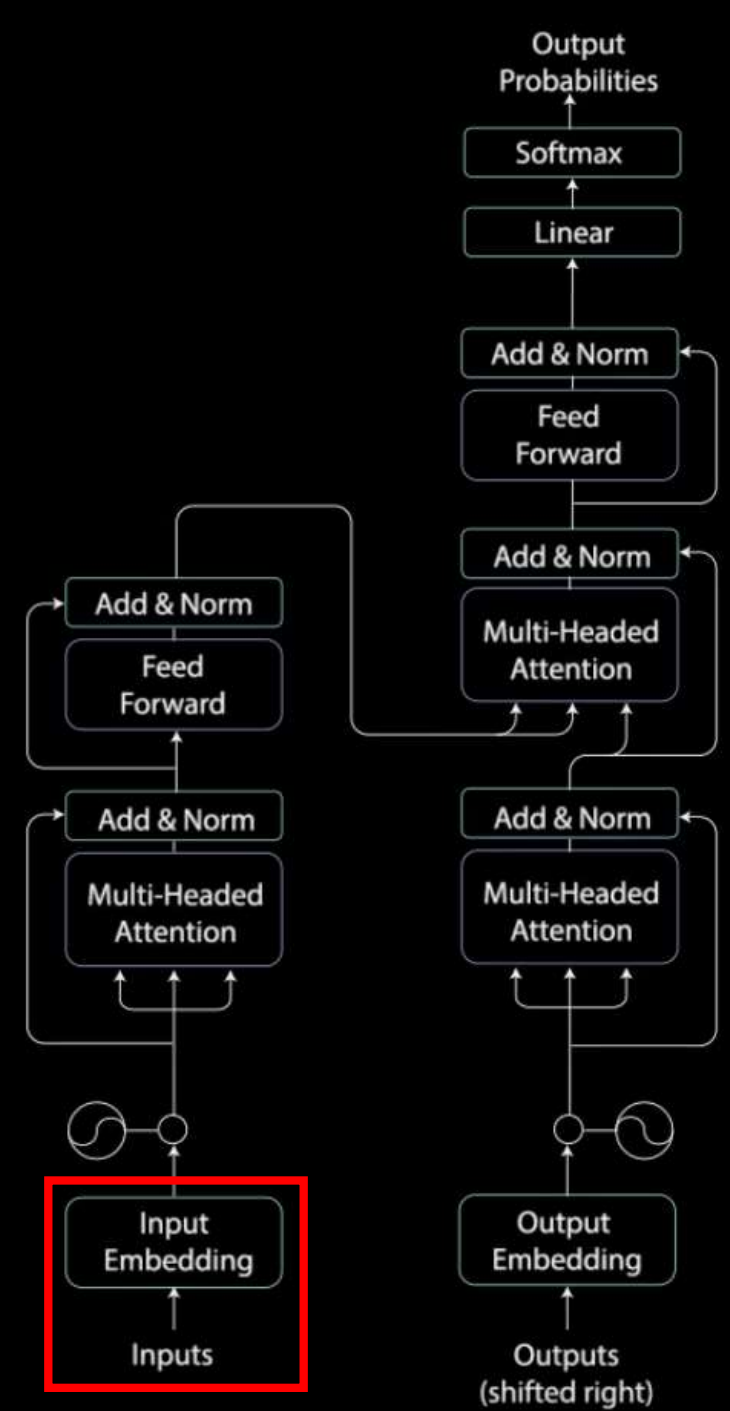

- Without any recurrence and convolutions.
- Referred to as NLP's ImageNet moment.
- It completely changed the landscape of deep learning models.
- Dominates modern deep learning.
- Key behind LLMs.

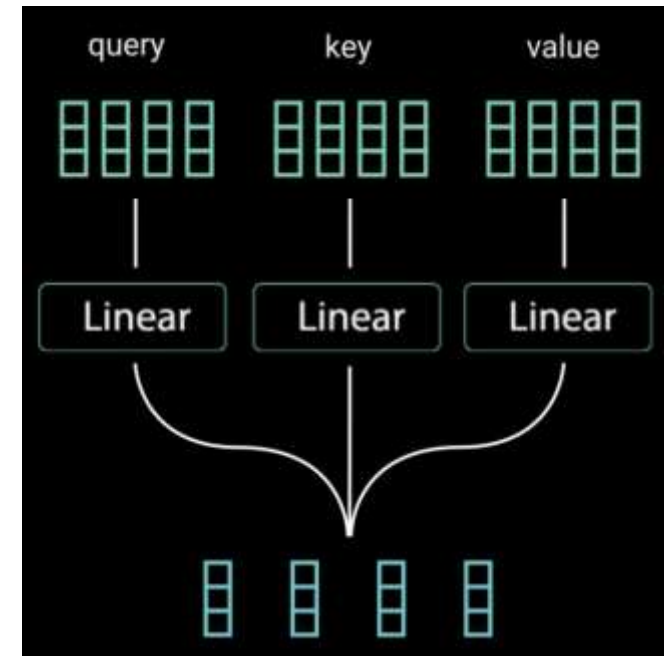

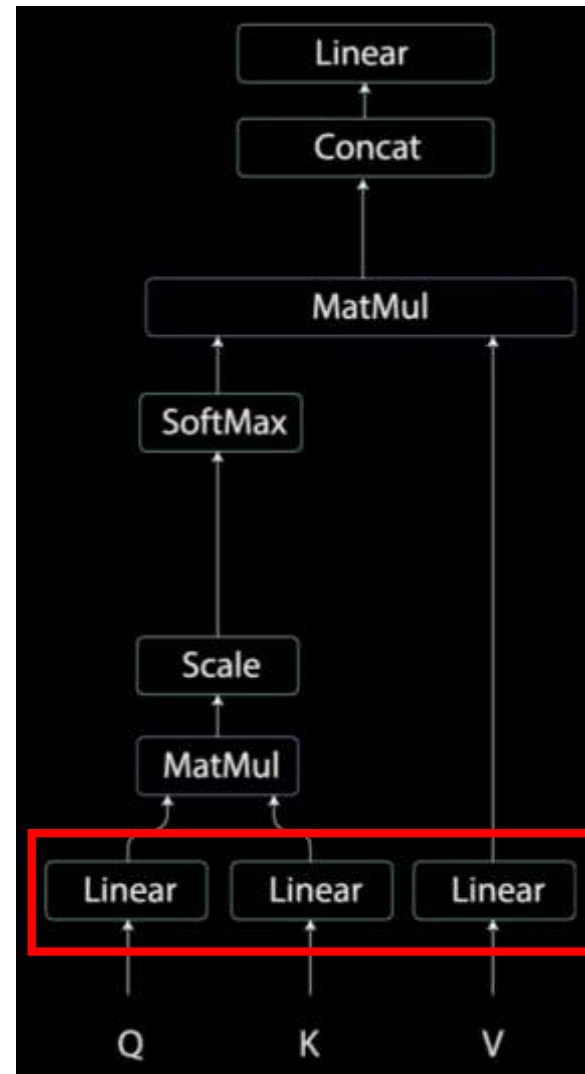

Important concepts:

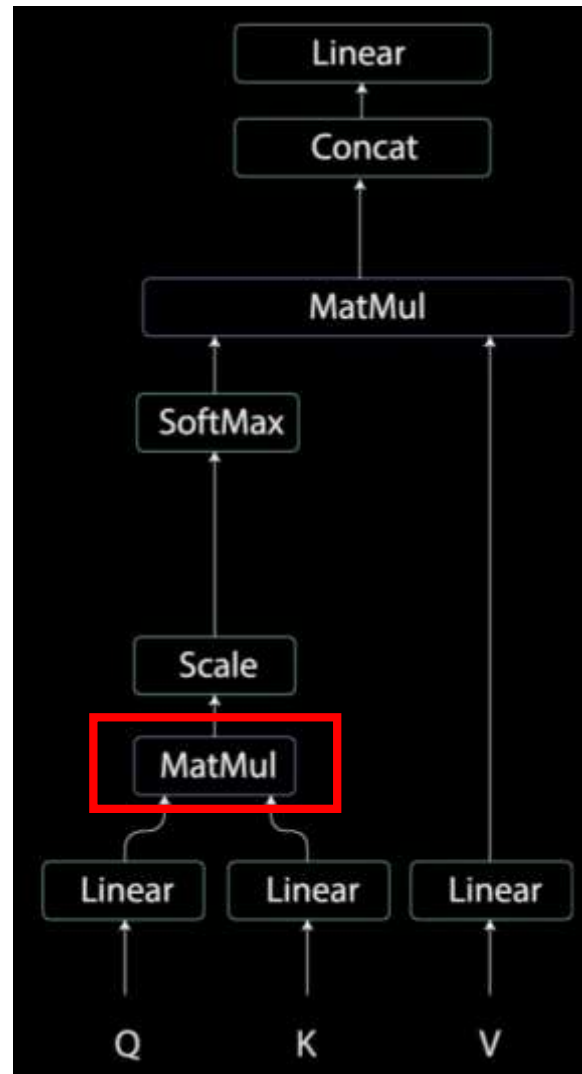

- Queries, keys, values.
- Scaled dot-product attention.
- Multi-head (self-)attention.

Understanding transformers: let's do a forward pass

	Hi	how	are	you
Hi	98	27	10	12
how	27	89	31	67
are	10	31	91	54
you	12	67	54	92

The diagram illustrates the calculation of Scaled Scores. It shows a 4x4 grid of orange squares representing the raw scores. This grid is divided by the square root of the number of attention heads, $\sqrt{d_k}$, to produce a 4x4 grid of teal squares representing the Scaled Scores.

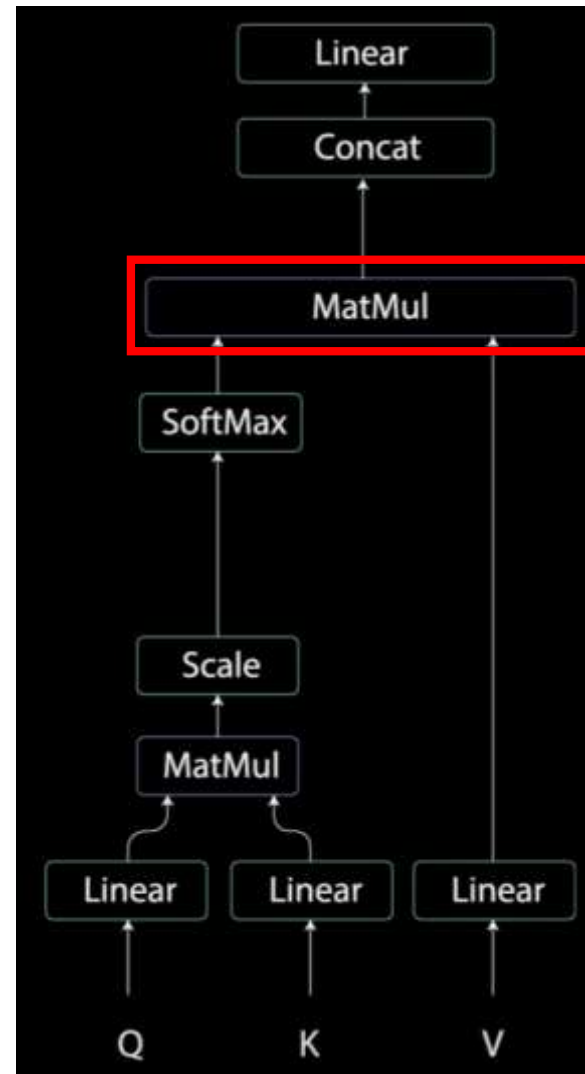

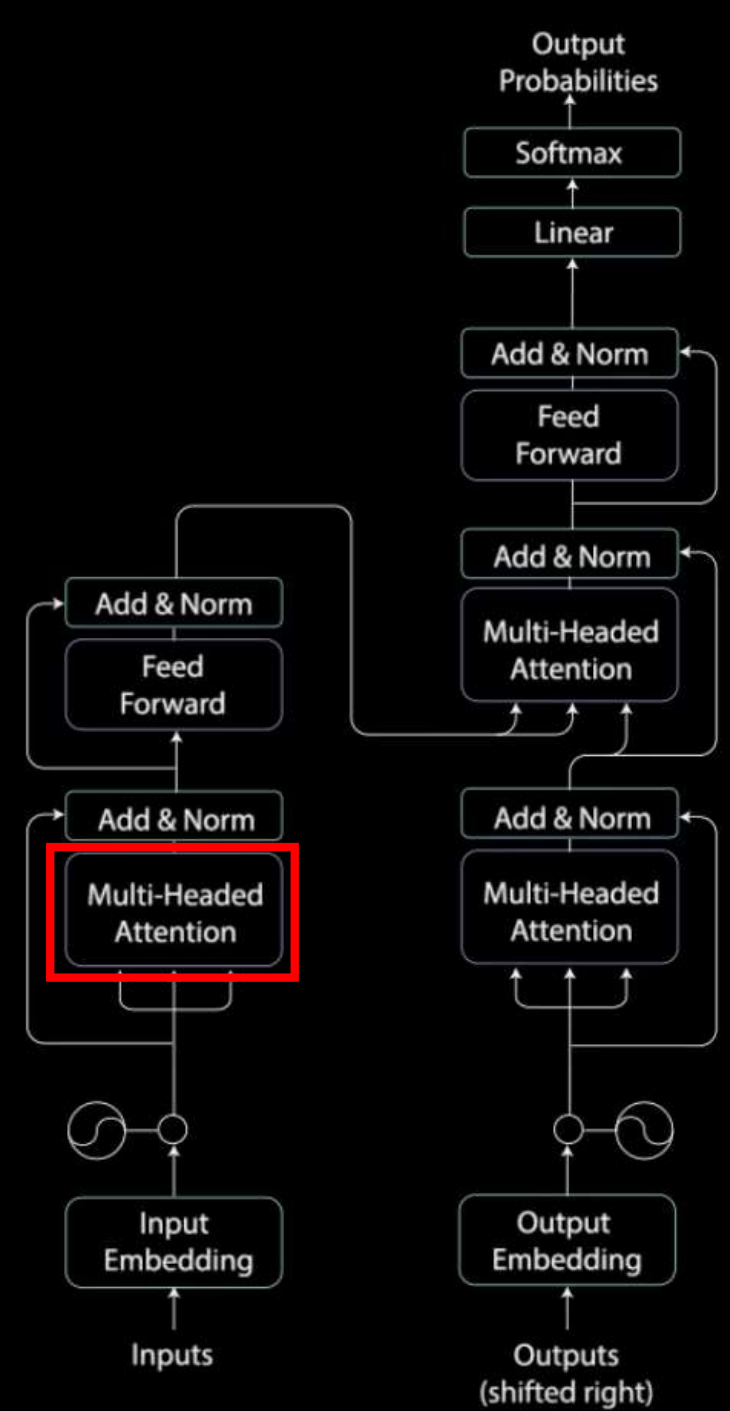

$$\frac{\text{4x4 Grid of Orange Squares}}{\sqrt{d_k}} = \text{4x4 Grid of Teal Squares (Scaled Scores)}$$

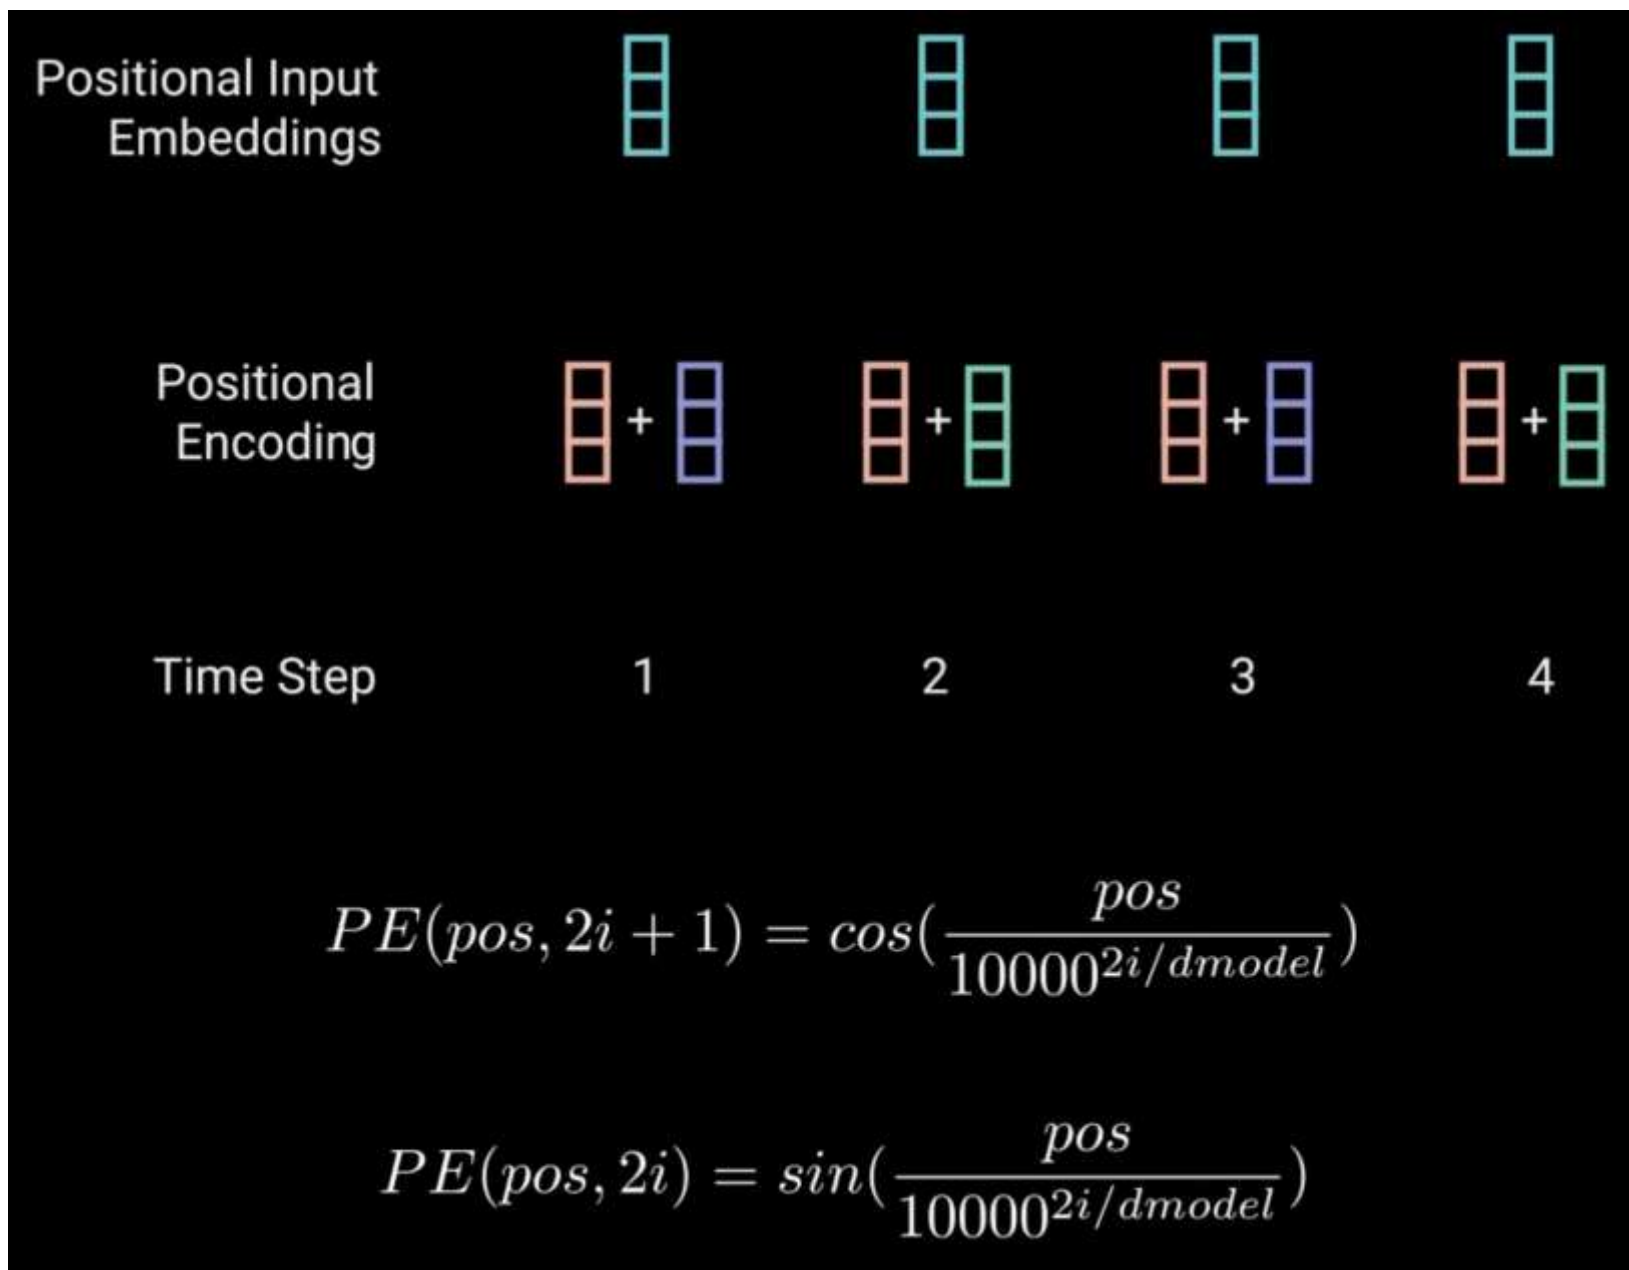

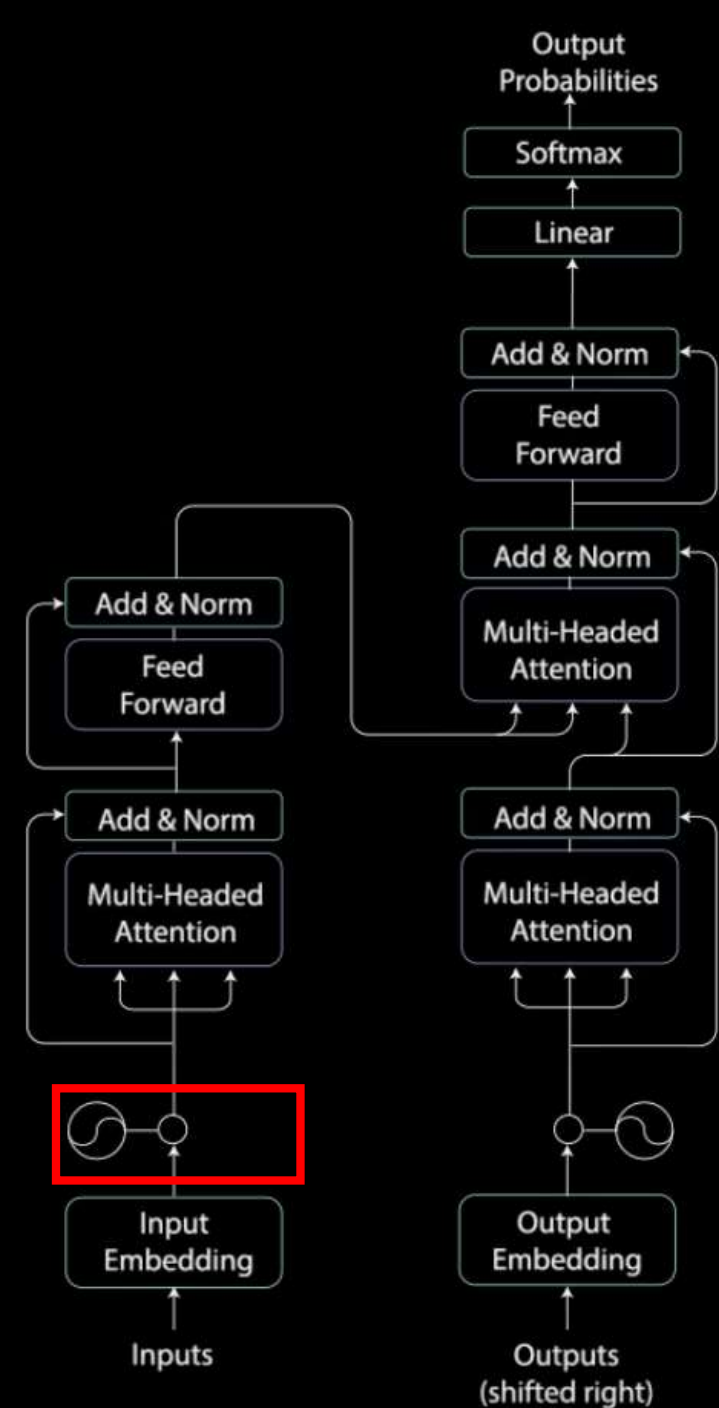

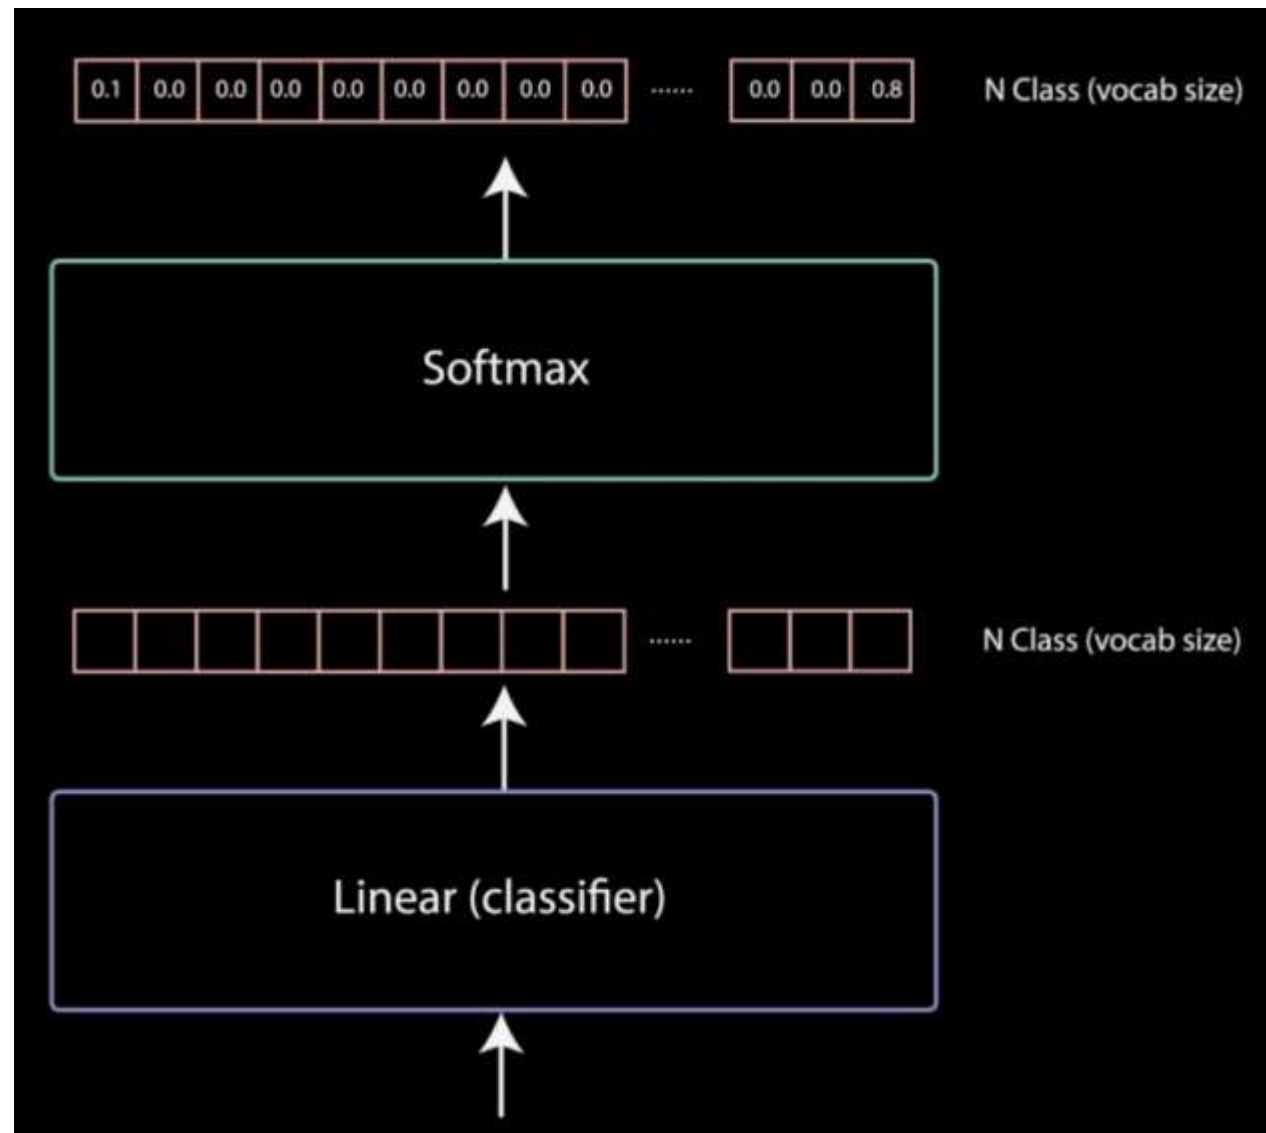

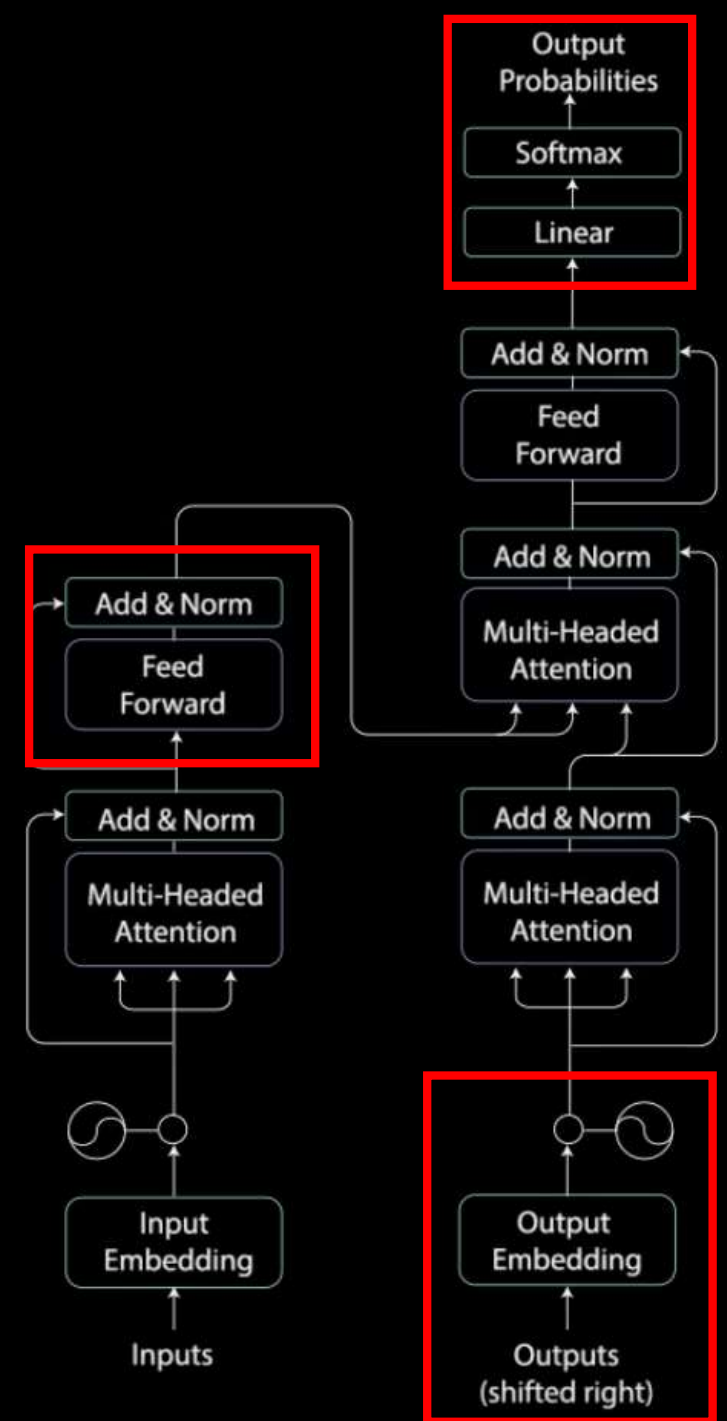

Softmax($\begin{bmatrix} 0.7 & 0.1 & 0.1 & 0.1 \\ 0.1 & 0.6 & 0.2 & 0.1 \\ 0.1 & 0.3 & 0.6 & 0.1 \\ 0.1 & 0.3 & 0.3 & 0.3 \end{bmatrix}$) =

	Hi	how	are	you
Hi	0.7	0.1	0.1	0.1
how	0.1	0.6	0.2	0.1
are	0.1	0.3	0.6	0.1
you	0.1	0.3	0.3	0.3

$$\text{softmax}(x)_i = \frac{\exp(x_i)}{\sum_j \exp(x_j)}$$

Queries, keys, and values

The Transformer paper redefines the attention mechanism by providing a generic definition based on **queries**, **keys**, **values**.

Intuition: Use the **query** of the target and the **key** of the input to calculate a matching score.

These scores act as the weights of the **values**.

The diagram illustrates the transformation of an input matrix X (represented as a 3x4 green grid) into three separate matrices: Q (query, 3x4 purple grid), K (key, 3x4 orange grid), and V (value, 3x4 blue grid). This is achieved by multiplying X by weight matrices W^Q , W^K , and W^V (each represented as a 4x4 grid of the same color as their respective output matrix). The equations shown are:

$$X \times W^Q = Q$$
$$X \times W^K = K$$
$$X \times W^V = V$$

The diagram shows the calculation of the attention weight matrix Z (pink 3x4 grid). It is derived by applying a softmax function to the scaled dot product of the query matrix Q (purple 3x4 grid) and the transpose of the key matrix K^T (orange 4x3 grid). The scaling factor is $\sqrt{d_k}$. The value matrix V (blue 3x4 grid) is then multiplied by the resulting weights to produce the final output Z .

$$Z = \text{softmax}\left(\frac{Q \times K^T}{\sqrt{d_k}}\right) \times V$$

The input consists of queries and keys of dimension d_k , and values of dimension d_v .

Compute the dot products of the query with all keys, divide each by $\sqrt{d_k}$, and apply a softmax function to obtain the weights on the values.

Attention: dot product with scaling

Attention mechanism in transformers are “scaled dot-product attention”.

Dot product computes similarity between queries and keys.

For large values of d_k the dot products grow magnitude, pushing the softmax function into with extremely small gradients.

The scaling by $\frac{1}{\sqrt{d_k}}$ counteracts this.

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right) V$$

Multi-headed attention

$$\text{MultiHead}(Q, K, V) = \text{Concat}(\text{head}_1, \dots, \text{head}_h)W^O,$$

$$W^O_i \in \mathbb{R}^{hd_v \times d_{\text{model}}}.$$

It is beneficial to linearly project the Q , K and V , h times with different, linear projections to d_k , d_k and d_v dimensions.

The attention function is performed in parallel, on each of these projected versions of Q , K and V .

These are concatenated and again projected, resulting in the final values.

Similar to the multiple

Multi-headed self-attention

For multi-head self-attention: the **queries**, **keys**, **values** are equal to the input representation or from the previous (encoding/decoding) layer.

- 1) This is our input sentence*
- 2) We embed each word*
- 3) Split into 8 heads. We multiply X or R with weight matrices
- 4) Calculate attention using the resulting $Q/K/V$ matrices
- 5) Concatenate the resulting Z matrices, then multiply with weight matrix W^O to produce the output of the layer

Thinking
Machines

...

* In all encoders other than #0, we don't need embedding. We start directly with the output of the encoder right below this one

$$\text{softmax}\left(\frac{Q \times K^T}{\sqrt{d_k}}\right) \times V$$

=

Break

Attention: dot product with scaling

Attention mechanism in transformers are “scaled dot-product attention”.

Dot product computes similarity between queries and keys.

For large values of d_k the dot products grow magnitude, pushing the softmax function into with extremely small gradients.

The scaling by $\frac{1}{\sqrt{d_k}}$ counteracts this.

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right) V$$

Multi-headed self-attention

For multi-head self-attention: the **queries**, **keys**, **values** are equal to the input representation or from the previous (encoding/decoding) layer.

- 1) This is our input sentence*
- 2) We embed each word*
- 3) Split into 8 heads. We multiply X or R with weight matrices

- 5) Concatenate the resulting Z matrices, then multiply with weight matrix W^O to produce the output of the layer

Thinking
Machines

...

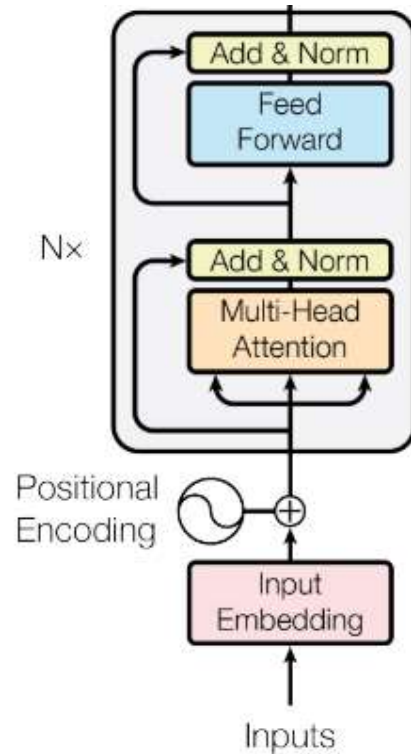

* In all encoders other than #0, we don't need embedding. We start directly with the output of the encoder right below this one

$$\text{softmax}\left(\frac{Q \times K^T}{\sqrt{d_k}}\right) \times V$$

=

Transformer encoder

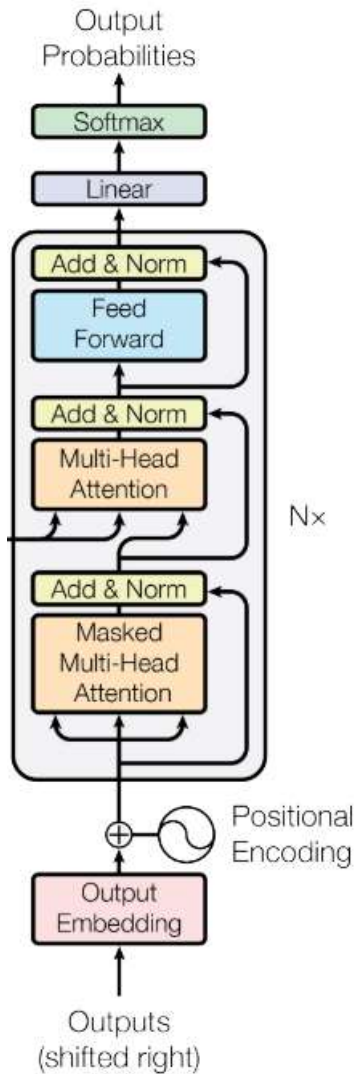

The encoder consists of $N = 6$ identical layers

Each encoder layer has 2 sub-layers: multi-head attention and fully connected feed-forward network.

Each sub-layer has a residual connection around it, followed by layer normalization.

Transformer decoder

- The decoder also consists of $N = 6$ identical layers
- A decoder layer is identical to the encoder layer,
 - It has an additional 3rd sub-layer,
 - Performs multi-head attention over the output of the encoder.

The masked self-attention sub-layer in the decoder prevents positions from attending to subsequent positions.

- the predictions for on the known outputs

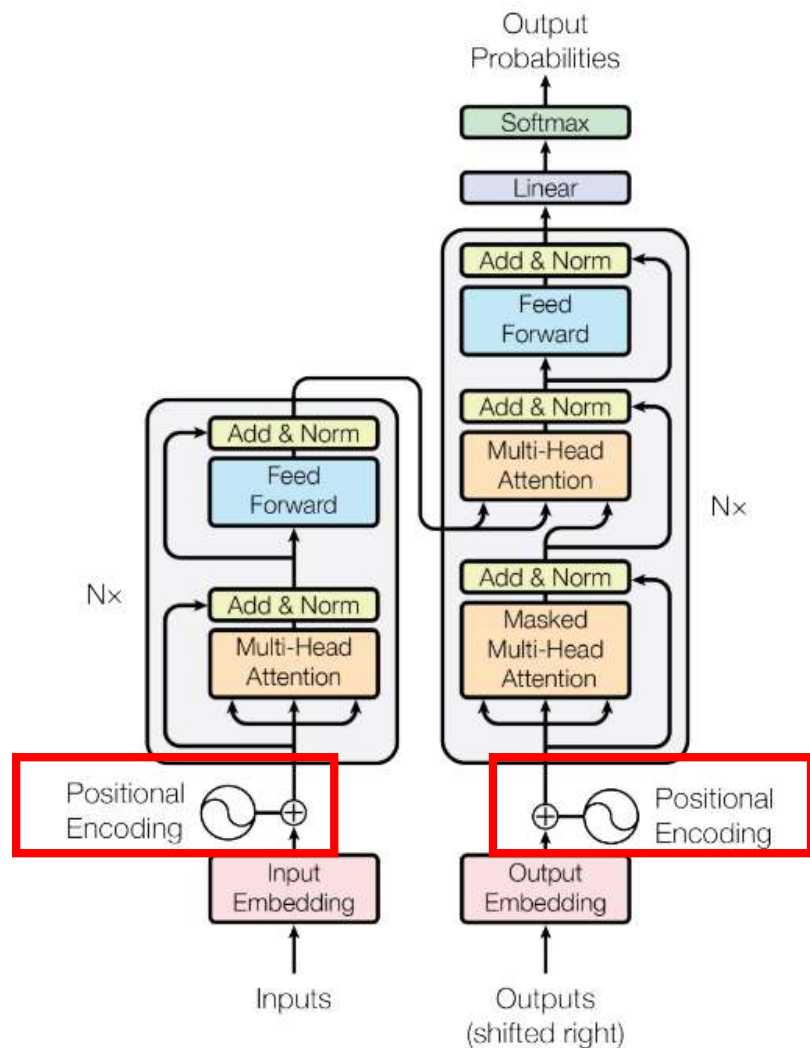

Position encoding

Attention is a permutation-invariant operation.

A pure attention module will return the same output regardless of the order of its inputs.

Solution: Positional encodings are added to the input in order to make use of the order of the sequence.

Positional encoding in the transformer

Intuitively: Positional encodings follow a specific pattern that the model learns

To determine the position of each word / the distance between words in the sequence.

Encode spatial, temporal, and modality identity... they can be learned or fixed.

The original Transformer uses sine and cosine functions of different frequencies:

$$PE_{(pos, 2i)} = \sin(pos/10000^{2i/d_{model}})$$

$$PE_{(pos, 2i+1)} = \cos(pos/10000^{2i/d_{model}})$$

Positional encoding in code

```
class PositionalEncoding(nn.Module):
    def __init__(self, d_model: int, dropout: float = 0.1, max_len: int = 5000):
        self.dropout = nn.Dropout(p=dropout)
        position = torch.arange(max_len).unsqueeze(1)
        div_term = torch.exp(torch.arange(0, d_model, 2) * (-math.log(10000.0) / d_model))
        pe = torch.zeros(max_len, 1, d_model)
        pe[:, 0, 0::2] = torch.sin(position * div_term)
        pe[:, 0, 1::2] = torch.cos(position * div_term)

    def forward(self, x: Tensor) -> Tensor:
        """ Args: x: Tensor, shape [seq_len, batch_size, embedding_dim] """
        x = x + self.pe[:x.size(0)]
        return self.dropout(x)
```

Pros:

- Transformer operates on data in parallel which accelerates the learning process, compared to RNN which operates sequentially
- Transformer can deal with long-term

Cons:

- Transformer scales quadratically with the number of inputs
- They are memory-intensive and require lots of data and long training

Summary

Encoder-decoder is a useful architecture for many deep learning problems

Traditional encoder-decoder for NMT has the issue with the context vector

Attention mechanism overcomes the problem, by learning to select important features

Transformer is the first model that entirely relies on attention.

BERT: **B**idirectional **E**ncoder **R**epresentations from **T**ransformers

Idea: pre-train
bidirectional
representations from
unlabeled text, by
jointly conditioning on
both left and right
context.

A pre-trained BERT
model can be fine-tuned
with just one
additional output layer
to create SOTA models
for NLP tasks.

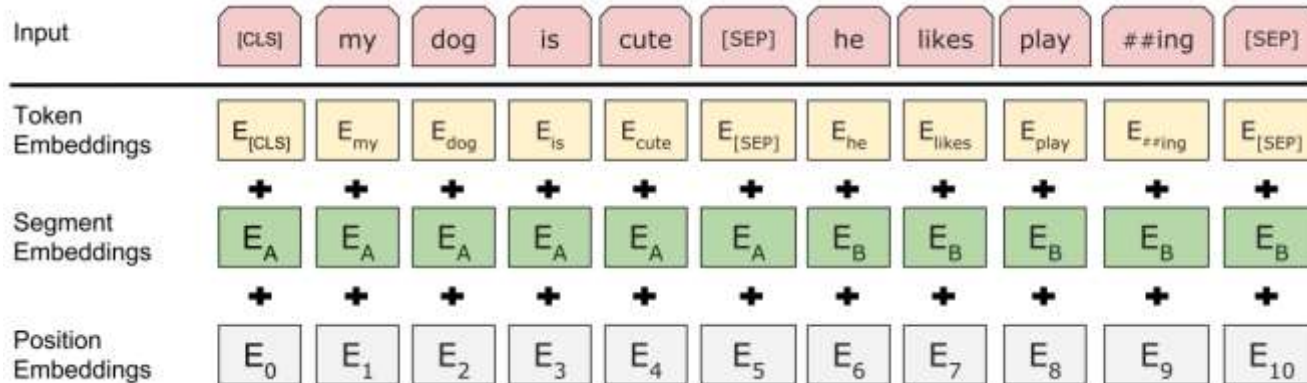

BERT input representation

The input representation: single sentence OR a pair of sentences in one sequence.

The complete input is the sum of the token embeddings, the segmentation embeddings and the position embeddings.

The first token of every sequence is always a special classification token ([CLS]).

- The final hidden state corresponding to this token is used as the aggregate sequence representation for

Sentence pairs are packed together into a single sequence, separated with a special token ([SEP]).

Also, a learned embedding is added to every token indicating whether it belongs

BERT pre-training

Task #1: **M**asked **L**anguage **M**odelling (MLM)

- Mask a percentage of the input tokens at random with a special token [MASK], and then predict those masked tokens.

Task #2: **N**ext **S**entence **P**rediction (NSP)

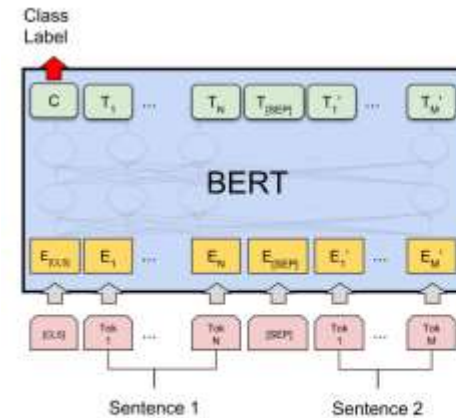

- Binary prediction whether the next sentences is a correct one.
- When choosing the sentences A and B, 50% of the time B is the actual next sentence that follows A and 50% of the time it is a random sentence from the corpus.

Datasets: BooksCorpus (800M words) and Wikipedia (2,500M words)

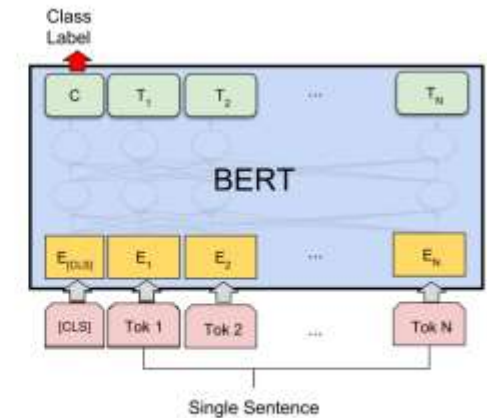

BERT fine-tuning

Fine-tuning is straightforward since the self-attention mechanism allows BERT to model many downstream tasks.

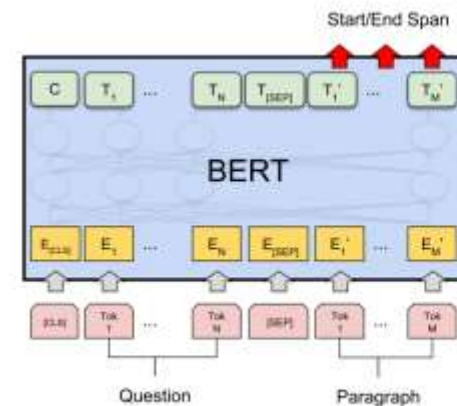

It is relatively inexpensive compared to pre-training.

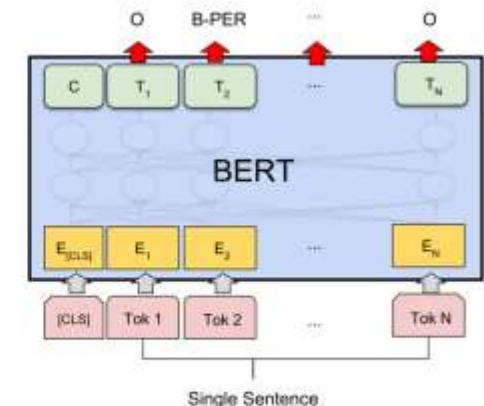

(a) Sentence Pair Classification Tasks:
MNLI, QQP, QNLI, STS-B, MRPC,
RTE, SWAG

GPT

Generative **P**retraining by **T**ransformers == GPT¹

- A pre-trained unidirectional Transformer decoder

The idea: To train a generative language model using “unlabeled” data.

And then fine-tune it on specific downstream tasks.

Unsupervised pre-training:

- Given an unsupervised corpus of

GPT 1 to 3

GPT1¹ : Proves that language modeling serves as an effective pre-training objective which helps the model to generalize well

GPT2² : uses a larger dataset for training and adds additional parameters to build a stronger language model.

GPT3³ : even larger than GPT2, can automatically generate high-quality paragraphs.

- Performs well on tasks on which it was never explicitly trained on, like writing SQL natural language descriptions

	GPT-1	GPT-2	GPT-3
Parameters	117 Million	1.5 Billion	175 Billion
Decoder Layers	12	48	96
Hidden Layer	768	1600	12288
Batch Size	64	512	3, 2M

¹ Improving Language Understanding by Generative Pre-Training, Radford et al. (2018)

² Language Models are Unsupervised Multitask Learners, Radford et al. (2019)

³ Language Models are Few-Shot Learners, Radford et al. (2020)

GPT enables in-context learning

The three settings we explore for in-context learning

Zero-shot

The model predicts the answer given only a natural language description of the task. No gradient updates are performed.

```
1 Translate English to French:  ← task description
2 cheese => _____        ← prompt
```

One-shot

In addition to the task description, the model sees a single example of the task. No gradient updates are performed.

```
1 Translate English to French:  ← task description
2 sea otter => loutre de mer    ← example
3 cheese => _____          ← prompt
```

Few-shot

In addition to the task description, the model sees a few examples of the task. No gradient updates are performed.

```
1 Translate English to French:  ← task description
2 sea otter => loutre de mer    ← examples
3 peppermint => menthe poivrée ← examples
4 plush giraffe => girafe peluche ← examples
5 cheese => _____          ← prompt
```

Traditional fine-tuning (not used for GPT-3)

Fine-tuning

The model is trained via repeated gradient updates using a large corpus of example tasks.

GPT versus BERT

The key difference between the BERT and GPT, is that GPT is a unidirectional Transformer decoder, whereas BERT is bidirectional Transformer encoder.

GPT outputs one token at a time, just like traditional language models.

- *After each token is produced, that token is added to the sequence of inputs.*
- *That new sequence becomes the input to the model in its next step.*
- *This is an idea*

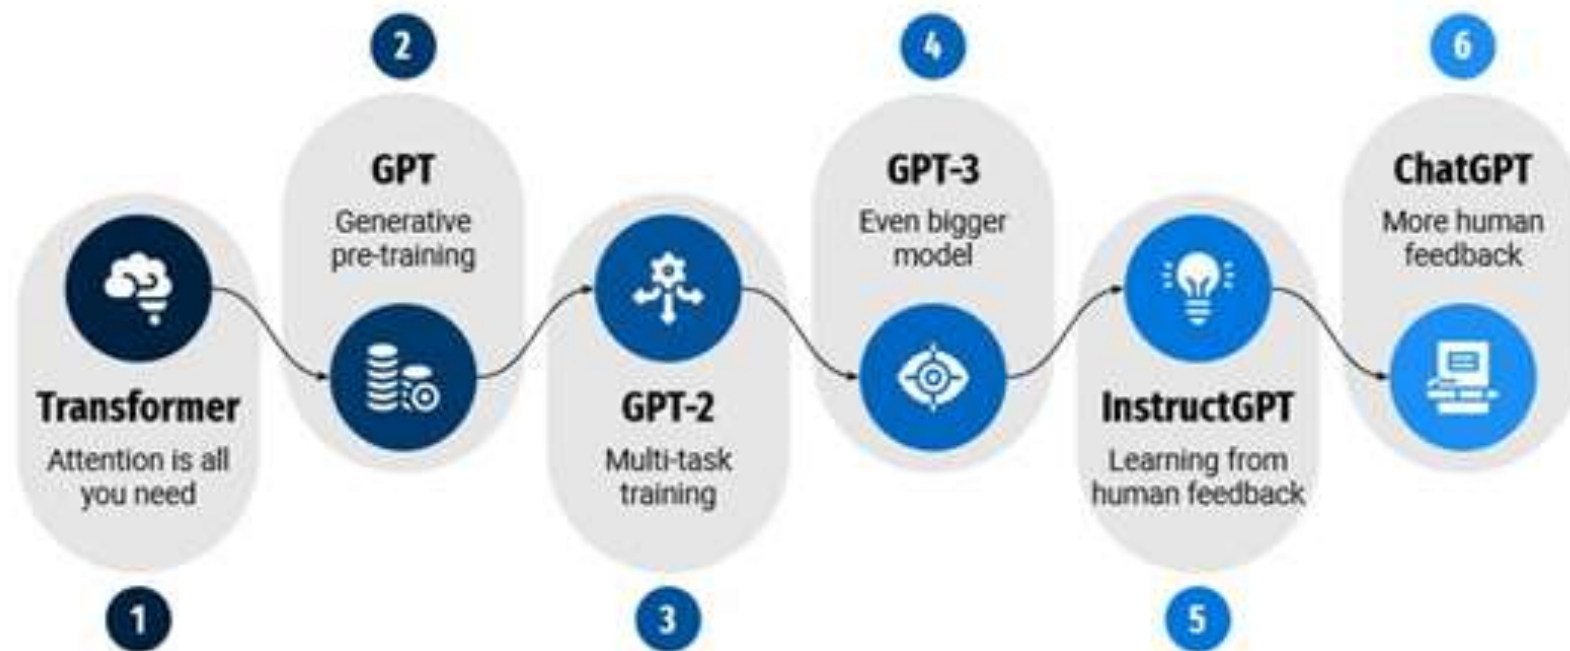

In losing auto-rec
incorporate the co

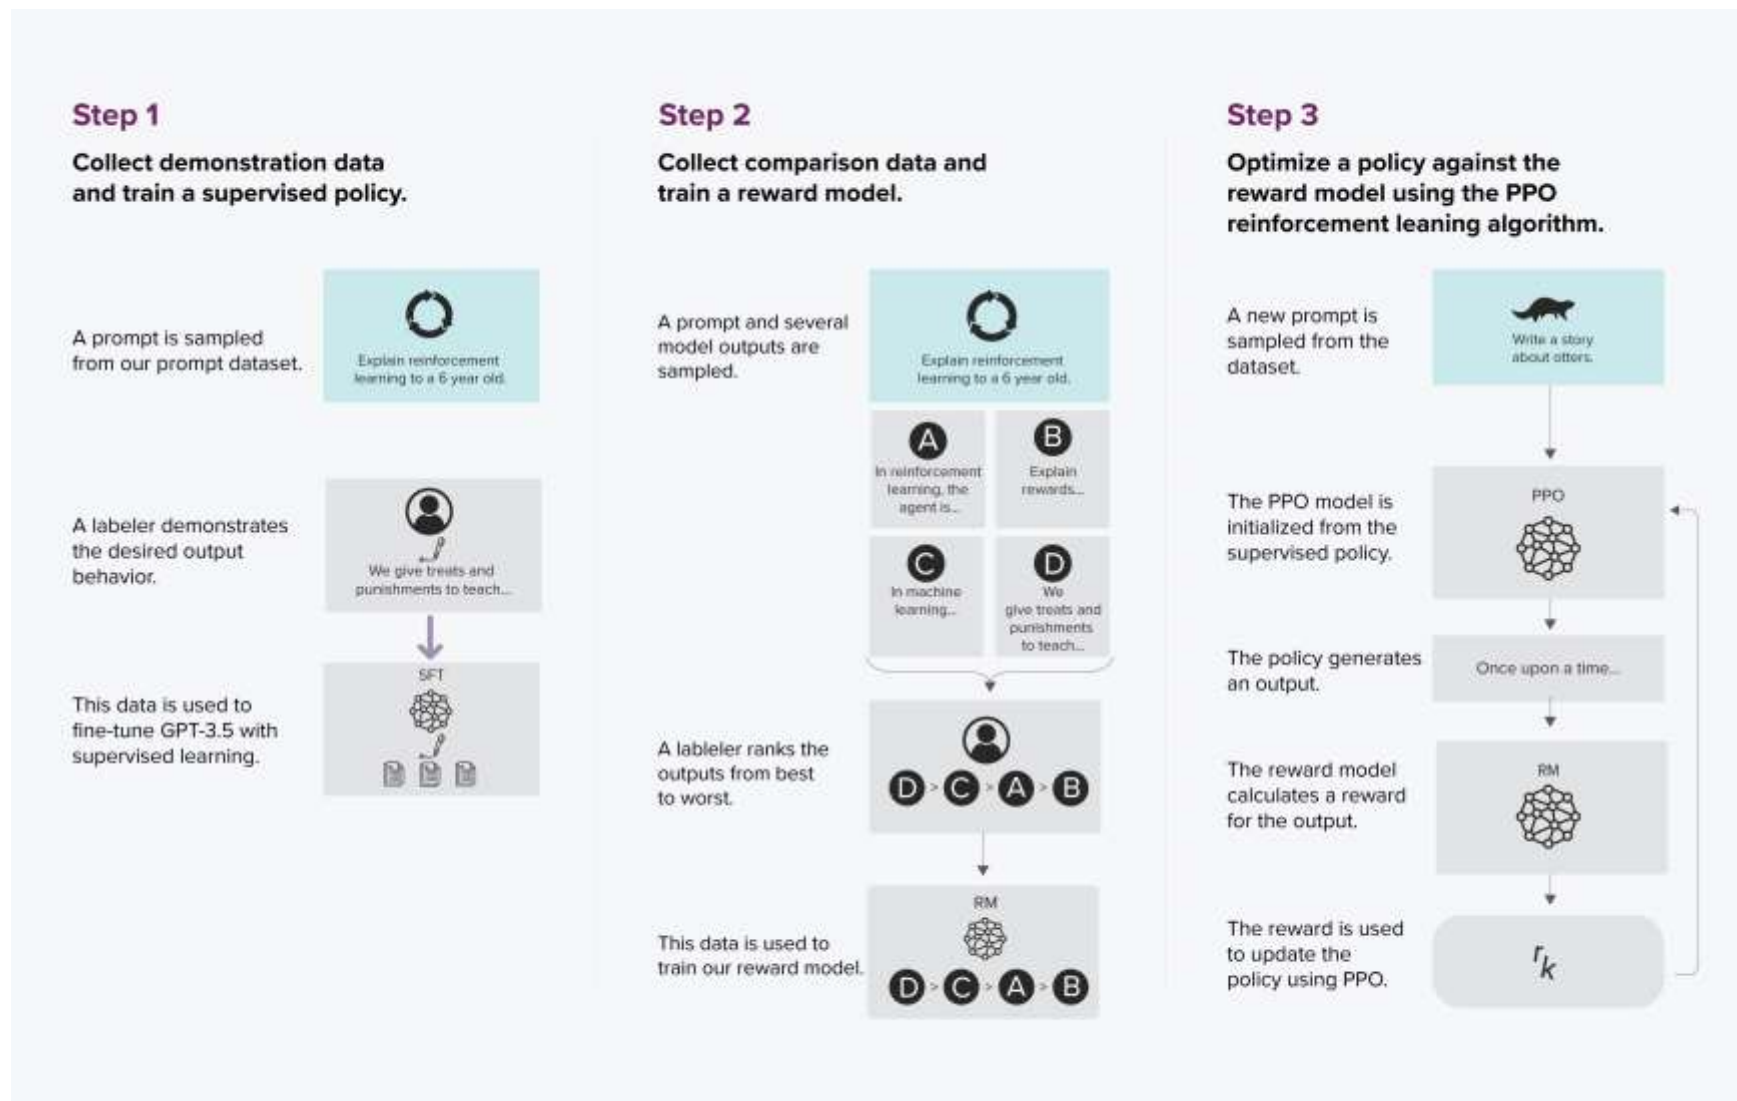

n ".

the ability to
f a word.

What is ChatGPT?

Reinforcement learning from human feedback

Why is ChatGPT so convincing

It is a result of exposure to extreme scale.

It's network consists of billions of parameters.

It is a product of careful and elaborate hyperparameter tuning.

Human feedback RL creates output formats that we like.

In short, ChatGPT has condensed the internet and gives it to us in a pleasing narrative style.

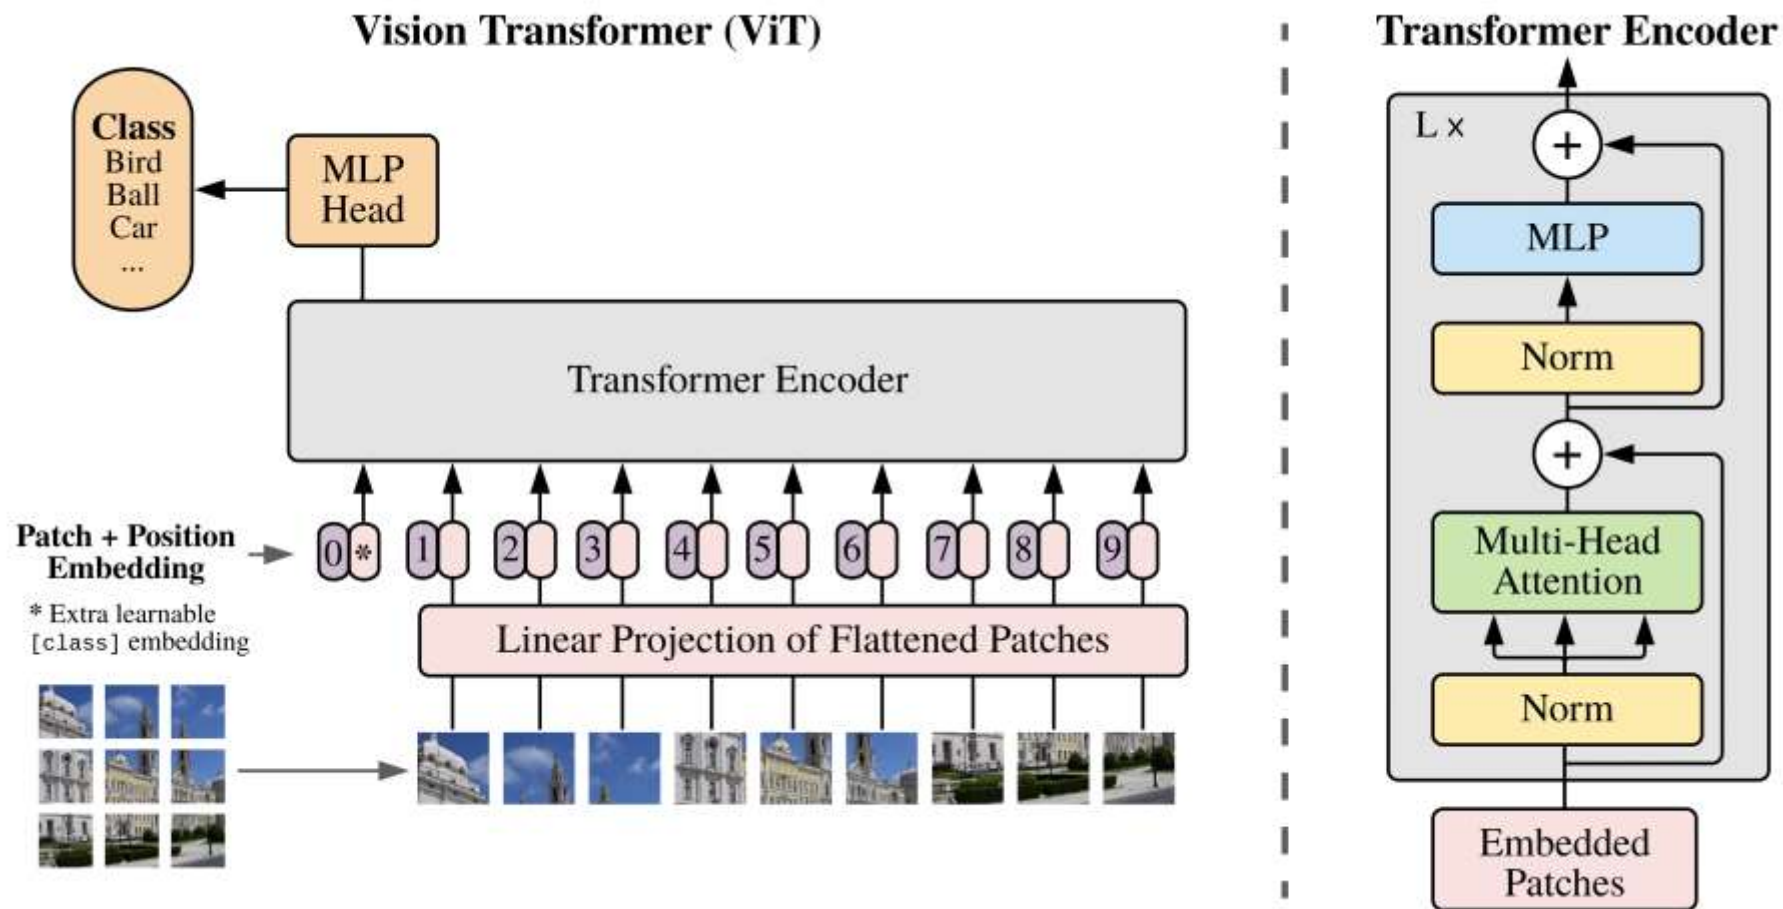

Vision transformers

Attention for text is intuitive, but it has also proven to be important for vision.

Transformers assume the input is a sequence of tokens.

What is a token in the context of an image?

Vision Transformer (ViT)

Vision Transformer (ViT)

Like BERT's [CLS] token, a learnable embedding is prepended to the sequence of embedded patches:

- the classification is done on this token (with an MLP)

“Position encodings” are added to the patch embeddings to retain positional information. (attention by itself doesn't have any notion of ordering/space)

- These vectors are also simply learned

```
# pos_embed has entry for class token, concat then add
if self.cls_token is not None:
    x = torch.cat((self.cls_token.expand(x.shape[0], -1, -1), x), dim=1)
    x = x + self.pos_embed
```

Attention versus convolution

Convolution is local and shared.

Attention is global.

Hence both bring different views to visual representation learning.

Transformers impose less structure, useful in large-scale settings.

Training a ViT is more difficult

Original paper required pre-training on ImageNet-22k (14M images) to achieve good performances.

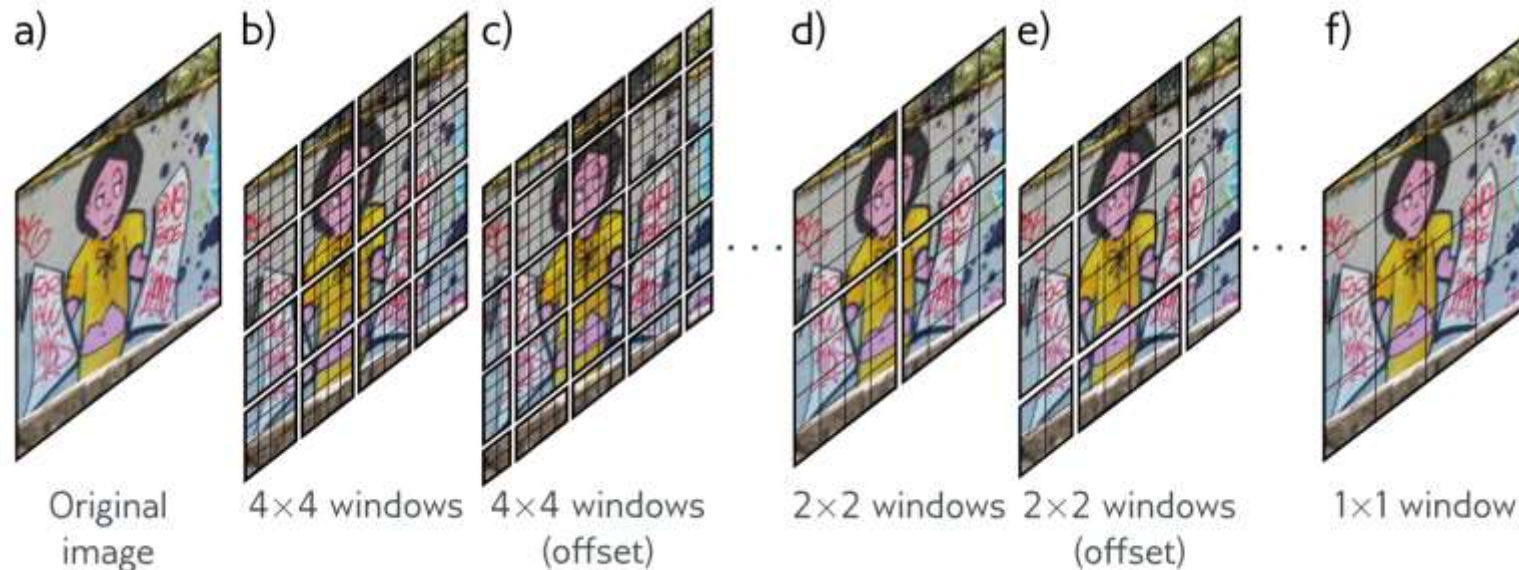

DeiT (data efficient image transformers) paper showed training with ImageNet-1k possible if more augmentations and regularisations are used.
